**Disclaimer.** This document explains the **implemented** daily emission and settlement mathematics. It does **not** promise profits, guaranteed yields, or fixed APYs. Outcomes depend on participation, skill, treasury health  $\backslash(G\backslash)$ , NFT identity (Alpaca / Cougar / traits), and market conditions for  $\$HANSOME$  and NFTs. Nothing herein is investment advice.

**Sources of truth (formulas):** `EmissionController.sol`, `SettlementLib.sol`, `GameTypes.sol`, `GameTreasury.sol`, GDS v1.1. Token **supply** of  $\$HANSOME$  (1,000,000,000 fixed) is unchanged by gameplay emission — rewards are paid from the **GameTreasury** balance, not minted.

### Abstract

HANSOME is an asymmetric day-settled GameFi economy on Robinhood Chain. Each day a bounded reward pool  $\backslash(R_d\backslash)$  is drawn from GameTreasury spendable balance  $\backslash(G\backslash)$ . That pool is split into Alpaca, Cougar Base, and Hunting sub-pools. Players compete through Commit → Reveal → Settlement → Claim. Emission bands shrink  $\backslash(R_d\backslash)$  as  $\backslash(G\backslash)$  falls, protecting longevity. Penalties, dust, and empty-pool remainders return to the Treasury rather than leaking value. The design aims for **two-sided value**: active players earn contingent rewards and utility; the ecosystem retains a sustainable runway, engagement, and token utility without unlimited inflation.

## 1. Game Economic Model — Daily Emission

### 1.1 Core relation

$$R_d = f(G)$$

where:

- $\backslash(G)$  = GameTreasury **spendable** balance of  $\$HANSOME$

$$\backslash(\displaystyle G = \mathrm{balance} - \mathrm{outstandingClaims})$$

- $\backslash(R_d)$  = that day's **fixed** reward pool (whole tokens, 18 decimals on-chain)
- $\backslash(f)$  is a **step function** of  $\backslash(G)$  relative to fixed reference  $\backslash(G_0)$  (not a floating high-water mark)

## 1.2 Implemented parameters

| Symbol                          | Value                                             | Role                                      |
|---------------------------------|---------------------------------------------------|-------------------------------------------|
| $\backslash(G_0)$               | $\backslash(300\{,}000\{,}000\backslash)$ HANSOME | Band reference ("initial treasury" scale) |
| $\backslash(G_{\mathrm{safe}})$ | $\backslash(15\{,}000\{,}000\backslash)$ HANSOME  | Safe-mode threshold                       |
| $\backslash(R_0)$               | $\backslash(400\{,}000\backslash)$ HANSOME        | Top-band daily pool                       |

## 1.3 Emission bands (on-chain)

| Condition                                                    | Daily pool $\backslash(R_d)$                                  |
|--------------------------------------------------------------|---------------------------------------------------------------|
| $\backslash(G \geq 0.70\backslash G_0)$                      | $\backslash(400\{,}000\backslash)$                            |
| $\backslash(0.40\backslash G_0 \leq G < 0.70\backslash G_0)$ | $\backslash(280\{,}000\backslash)$                            |
| $\backslash(0.20\backslash G_0 \leq G < 0.40\backslash G_0)$ | $\backslash(160\{,}000\backslash)$                            |
| $\backslash(G_{\mathrm{safe}} \leq G < 0.20\backslash G_0)$  | $\backslash(80\{,}000\backslash)$                             |
| $\backslash(G < G_{\mathrm{safe}})$                          | $\backslash(0\backslash)$ (+ Commit paused in implementation) |

Numeric thresholds for  $\backslash(G_0 = 300\{,}000\{,}000\backslash)$ :

| Band floor                       | $\backslash(G)$                           |
|----------------------------------|-------------------------------------------|
| $\backslash(0.70\backslash G_0)$ | $\backslash(210\{,}000\{,}000\backslash)$ |
| $\backslash(0.40\backslash G_0)$ | $\backslash(120\{,}000\{,}000\backslash)$ |
| $\backslash(0.20\backslash G_0)$ | $\backslash(60\{,}000\{,}000\backslash)$  |
| $\backslash(G_{\mathrm{safe}})$  | $\backslash(15\{,}000\{,}000\backslash)$  |

## 1.4 Mathematical purpose

1. **No unlimited emission** —  $\backslash(R_d)$  is capped per day and cannot grow with "demand" alone.
2. **Treasury longevity** — as  $\backslash(G)$  declines,  $\backslash(R_d)$  steps down, extending runway.
3. **Incentive preservation** — while  $\backslash(G \geq G_{\mathrm{safe}})$ , a positive pool remains (until safe mode).
4. **No mint** — settlement never mints  $\$HANSOME$  ; it only **reserves** and later **transfers** from GameTreasury.

## 2. Daily Reward Distribution Formula

### 2.1 Pool split (exact)

$$\begin{aligned}
 R_d^A &= \left\lfloor R_d \times 0.80 \right\rfloor, \\
 R_d^C &= \left\lfloor R_d \times 0.10 \right\rfloor, \\
 R_d^H &= \left\lfloor R_d \times 0.10 \right\rfloor
 \end{aligned}$$

$$\mathrm{splitDust} = R_d - R_d^A - R_d^C - R_d^H$$

( SettlementLib.splitDailyPool — integer division; dust returns to Treasury via unallocated.)

### 2.2 Conceptual player reward

A useful pedagogical decomposition (maps to on-chain terms below):

$$\begin{aligned}
 &\mathrm{Reward}_i \\
 &\approx \\
 &\underbrace{\frac{R_{\mathrm{pool}}}{\sum_j W_j}}_{\text{pool share}} \\
 &\cdot \\
 &\underbrace{(1 - \pi_i)}_{\text{survival / hunt risk}} \\
 &\cdot \\
 &\underbrace{\tau_i}_{\text{trait effects}}
 \end{aligned}$$

#### On-chain Alpaca (precise):

1. Location weight  $w(L) \in \{1, 2, 3, 5, 8\}$  (Home...River).
2. Effective weight numerator: Farmer uses  $(1.20 \times w(L))$ , else  $w(L)$ .
3. Gross:  $r_i^A, \mathrm{gross} = R_d^A \cdot \omega_i / \Omega_d$  (last participant absorbs dust).
4. Penalty rate  $\pi_i$  from location pressure + traits (King / Guardian / Lucky / Runner).
5. Net credited:  $r_i^A, \mathrm{net} = r_i^A, \mathrm{gross} (1 - \pi_i)$ .

#### On-chain Cougar (precise):

1. Base: equal split of  $R_d^C$  among valid Cougars.

2. Hunt: if location huntable and  $\geq 1$  Alpaca there, share of  $\backslash(R_d^H)\backslash$  proportional to Alpaca count at that location; else hunt share 0 and  $\backslash(R_d^H)\backslash \rightarrow$  dust/unallocated.

## 2.3 Worked example (illustrative, not a forecast)

Assume  $\backslash(R_d = 400\{, \}000)\backslash$ , so  $\backslash(R_d^A=320\{, \}000)\backslash$ ,  $\backslash(R_d^C=40\{, \}000)\backslash$ ,  $\backslash(R_d^H=40\{, \}000)\backslash$ .

**Example A — two Alpacas, no Cougars, both at Grassland ( $\backslash(w=3)\backslash$ ), Common class,  $\backslash(\pi=0)\backslash$ :**

$$\begin{aligned}\backslash\Omega &= 3+3 = 6, \backslash\text{quad} \\ r_1 &= r_2 = 320\{, \}000 \backslash\text{times} \backslash\text{frac}\{3\}\{6\} = 160\{, \}000\end{aligned}$$

$\backslash(R_d^C+R_d^H)\backslash$  become unallocated (no Cougars) and stay in Treasury.

**Example B — one Common Alpaca and one Cougar both at Grassland; Alpaca faces pressure:**

- Alpaca receives gross from  $\backslash(R_d^A)\backslash$ , then net after  $\backslash(\pi > 0)\backslash$ .
- Cougar receives base  $\backslash(R_d^C)\backslash$  (alone  $\Rightarrow$  all of it) plus hunt share of  $\backslash(R_d^H)\backslash$  if hunt succeeds.
- Penalties from Alpaca return to Treasury (not paid to the Cougar wallet).

## 3. Alpaca vs Cougar Economic Model

| Dimension        | Alpaca                                                                               | Cougar                                                                        |
|------------------|--------------------------------------------------------------------------------------|-------------------------------------------------------------------------------|
| Supply (Genesis) | 500                                                                                  | 50                                                                            |
| Pool access      | $\backslash(R_d^A)\backslash$ (80%)                                                  | $\backslash(R_d^C)\backslash$ (10%) + $\backslash(R_d^H)\backslash$ (10%)     |
| Income drivers   | Location weight, Farmer +20% weight, trait mitigation of $\backslash(\pi)\backslash$ | Equal base split; hunt share if co-located with Alpacas                       |
| Primary risk     | Hunting penalty $\backslash(\pi)\backslash$ at non-Home locations                    | Failed hunts ( $\backslash(R_d^H)\backslash$ dust); competition among Cougars |
| Home             | Allowed (safe from hunt $\backslash(\pi^0=0)\backslash$ )                            | Illegal (invalid day)                                                         |
| Traits           | King / Guardian / Farmer / Lucky / Runner / Common                                   | None (uniform $\backslash(w^C=1)\backslash$ )                                 |

**Demand for gameplay:** Alpacas create “prey density” that makes Hunting Pool meaningful; Cougars create risk that makes location and trait choice meaningful. Neither side’s rewards are automatic — both require valid Commit + Reveal.

## 4. Game Theory Analysis

### 4.1 Expected value (decision frame)

For a rational player deciding whether to acquire / play an NFT:

$$\begin{aligned} & \mathrm{EV} \\ &= \\ & \sum_{s \in S} \mathrm{Pr}(s) \cdot \mathrm{Reward}(s) \\ & - \\ & \mathrm{Cost} \end{aligned}$$

where  $S$  is the set of plausible day outcomes, and **Cost** may include NFT acquisition, opportunity cost, and gas — **not** protocol fees on rewards (claims are pull transfers of already-reserved amounts).

Players condition on:

- NFT acquisition cost and secondary-market liquidity
- Skill (location choice, when to risk River vs Home)
- Survival / hunt probabilities (endogenous to the day's cohort)
- Current  $G$  and thus  $R_d$  band

**Important:**  $\mathrm{EV}$  can be negative. High skill does not imply profit after NFT cost.

## 4.2 Population balance (Nash-style intuition)

Let  $n_A$ ,  $n_C$  be active Alpacas and Cougars on a day at overlapping locations.

- **Too many Cougars:** Base pool  $R_d^C$  splits thinner; hunt competition rises; Alpacas may hide at Home → fewer successful hunts →  $R_d^H$  dust ↑.
- **Too many Alpacas:** Alpaca gross shares dilute; Cougars enjoy denser hunt targets but Alpacas may spread across locations.
- **Balanced play:** Risk and reward remain interesting for both sides → higher engagement.

This is **not** a solved closed-form Nash equilibrium claimed by the protocol; it is a qualitative stability argument consistent with the asymmetric pool design (80/10/10).

## 4.3 Conservation identity (protocol invariant)

For each settled day:

$$\begin{aligned} R_d = & \underbrace{\mathrm{playerTotal}}_{\text{reserved for claims}} \\ & + \underbrace{P_d^{\mathrm{pen}}}_{\text{stays in Treasury}} \\ & + \underbrace{\mathrm{unallocated}}_{\text{dust + empty pools + failed hunt}} \} R_d^H \end{aligned}$$

So emission never “disappears”; unpaid pool mass remains spendable  $G$  (except amounts later claimed by players).

# 5. Treasury Sustainability Model

## 5.1 Gross runway (informational)

Ignoring sinks, penalty recycling, and band step-downs:

```

\text{Lifetime}_{\mathrm{gross}}
\approx
\frac{G_0}{R_0}
=
\frac{300\{, \}000\{, \}000}{400\{, \}000}
=
750 \text{ days}

```

## 5.2 Why actual lifetime differs

| Factor                              | Effect on runway                                                                                  |
|-------------------------------------|---------------------------------------------------------------------------------------------------|
| Emission step-downs                 | $(R_d)$ falls as $(G)$ falls → <b>longer</b> calendar life                                        |
| Penalties / unallocated / hunt dust | Stay in Treasury → <b>slower</b> net drain than $(R_d)$ per day                                   |
| Player claims                       | Reduce balance when paid                                                                          |
| Token sinks (players → Treasury)    | Can <b>increase</b> $(G)$                                                                         |
| Safe mode $(G < G_{\mathrm{safe}})$ | $(R_d=0)$ , Commit paused → freeze until rebuilt                                                  |
| Activity level                      | Low participation → more unallocated; high participation → more <code>playerTotal</code> reserved |

## 5.3 Funding intent

Operational launch planning targets GameTreasury near  $(G_0 = 300\{, \}000\{, \}000)$  so early days sit in the  $(R_d = R_0)$  band, subject to actual funded amount and subsequent dynamics.

## 6. Two-Sided Value Creation

| Players gain                        | Ecosystem gains                                  |
|-------------------------------------|--------------------------------------------------|
| ↑ Contingent reward opportunities   | ↑ Daily active participation                     |
| ↑ NFT utility (identity + traits)   | ↑ Retention via day loop                         |
| ↑ Competitive / entertainment value | ↑ Demand for Genesis NFTs                        |
| ↑ Agency (location, side, traits)   | ↑ <code>\$HANSOME</code> utility (claims, sinks) |
| ↑ Transparent, auditable math       | ↑ Sustainable emission discipline                |

A healthy GameFi economy requires **both** sides: unbounded player extraction without runway destroys the game; a full Treasury with no players creates no culture. HANSOME couples them through  $(G \mapsto R_d)$  and asymmetric roles.

## 7. Why HANSOME's Economy Is Designed for Long-Term Sustainability

This section explains **design intent**, not expected returns. Longevity depends on participation, funding of GameTreasury, ops quality, and markets. Nothing here guarantees profit for players or the project.

### 7.1 Comparison with traditional Play-to-Earn (P2E)

| Theme               | Typical historical P2E pattern                      | HANSOME approach (implemented)                                                                         |
|---------------------|-----------------------------------------------------|--------------------------------------------------------------------------------------------------------|
| Reward source       | Often continuous mint / inflationary emissions      | Rewards paid from <b>pre-funded GameTreasury</b> ; \$HANSOME supply is <b>fixed</b> (no gameplay mint) |
| Emission control    | Hard to stop once flywheel of "print → sell" starts | $R_d = f(G)$ <b>step bands</b> shrink the daily pool as $G$ falls; safe mode can halt Commits          |
| Player incentive    | Maximize extractable tokens today                   | Compete for a <b>bounded</b> daily pool via Commit / Reveal / skill                                    |
| Ecosystem incentive | Grow users even if emission is unsustainable        | Preserve runway so the day loop can remain meaningful longer                                           |
| Risk to holders     | Dilution from new mint                              | Dilution from gameplay mint is <b>structurally removed</b> ; market risk remains                       |

Traditional P2E often failed when emissions outran sinks and newcomers funded exits. HANSOME does not claim to eliminate market risk; it **removes unlimited reward minting** as a protocol lever and ties payouts to treasury health.

### 7.2 Fixed-supply token advantage

\$HANSOME is a **fixed-supply** ERC-20: the full supply was minted once at token deployment; there is no owner mint for gameplay rewards.

| Implication                        | Why it matters for sustainability                                           |
|------------------------------------|-----------------------------------------------------------------------------|
| Settlement never mints             | Claiming cannot inflate supply                                              |
| Game rewards = transfers           | Every HANSOME paid to players left GameTreasury (or was already outside it) |
| Tokenomics unchanged by this model | Game math does <b>not</b> rewrite total supply, taxes, or LP allocation     |

Fixed supply does **not** imply price support. It only means the game cannot "print its way" out of a reward schedule.

### 7.3 Treasury-controlled reward emission

Daily emission is gated by spendable treasury balance  $G$ :

$$R_d = f(G), \quad \text{quad}$$

$f$  is a decreasing step function of  $G$  relative to  $G_0$ .

- High  $G \rightarrow$  larger  $R_d$  (up to  $R_0 = 400,000$ ).
- Falling  $G \rightarrow$  automatic step-downs ( $280,000 \rightarrow 160,000 \rightarrow 80,000$ ).
- $G < G_{\text{safe}} \rightarrow R_d = 0$  and Commits paused in the implementation.

Penalties, split dust, empty-pool remainders, and failed-hunt  $R_d^H$  stay in the Treasury (conservation identity). Sinks can return tokens to  $G$ . Together, these mechanisms **slow net drain** relative to a naive “always pay full  $R_d$  with no recycling” model — without promising a fixed calendar lifetime.

## 7.4 Player vs ecosystem alignment

| If the design over-favors... | Failure mode                                           | HANSOME counterweight                                                         |
|------------------------------|--------------------------------------------------------|-------------------------------------------------------------------------------|
| Players only                 | Treasury empties; later cohorts get nothing meaningful | Emission bands + safe mode + no mint                                          |
| Ecosystem / Treasury only    | No reason to play; NFTs idle                           | Positive $R_d$ while $G \geq G_{\text{safe}}$ ; asymmetric pools; pull claims |
| Short-term extraction        | Dump pressure after farm                               | Bounded $R_d$ ; rewards require valid play each day                           |

Alignment means: **active play** is the path to contingent rewards, and **treasury health** is the path to continued emission. Neither side is promised a win; both are constrained by the same  $G$ .

## 7.5 Alpaca / Cougar two-sided gameplay economy

Sustainability is not only about  $G$ ; it is also about **keeping both roles interesting**:

- **Alpacas (80% pool)**: Location weight, traits, and hunting risk create strategic depth. Over-hunting pressure pushes Alpacas toward safer locations — which reduces Cougar hunt success.
- **Cougars (10% + 10% hunt)**: Need Alpaca presence to monetize the Hunting Pool; too many Cougars dilute base shares and can starve hunt opportunities.
- **Feedback loop**: Imbalance reduces EV for the overcrowded side  $\rightarrow$  players may switch roles or locations  $\rightarrow$  engagement stays competitive rather than one-sided farming.

A one-sided “only farm the high APY role” meta is what burned many P2E titles. The 80/10/10 split plus hunt dependency is intended to make **mutual demand for opponents** part of the economy — again without guaranteeing that any role is profitable after NFT cost.

## 7.6 What “long-term” does and does not mean

| This document claims                     | This document does <b>not</b> claim |
|------------------------------------------|-------------------------------------|
| Emission is bounded and treasury-linked  | Guaranteed years of rewards         |
| Fixed supply blocks reward inflation     | Guaranteed token price              |
| Two-sided play supports retention design | Guaranteed player profit            |

Gross runway at  $\lfloor G_0/R_0 \rfloor$  approx 750 days is an **illustration**

That illustration equals real calendar life

Sustainability here means **structural resistance to unlimited emission**, not a promise that the economy will always grow or that participants will earn net positive returns.

## 8. Example Scenarios

### Scenario A — High treasury health

| Item                  | Value                                                                                            |
|-----------------------|--------------------------------------------------------------------------------------------------|
| $\lfloor G \rfloor$   | $\lfloor \ge 210\{,000\{,000\} \rfloor \lfloor (0.70 \lfloor G_0 \rfloor) \rfloor$               |
| $\lfloor R_d \rfloor$ | $\lfloor 400\{,000\} \rfloor$                                                                    |
| Player impact         | Maximum designed daily pool                                                                      |
| Sustainability        | Fastest gross drain; still ~hundreds of days at $\lfloor R_0 \rfloor$ from $\lfloor G_0 \rfloor$ |

### Scenario B — Medium treasury

| Item                  | Value                                                                        |
|-----------------------|------------------------------------------------------------------------------|
| $\lfloor G \rfloor$   | e.g. $\lfloor 120\{,000\{,000\} \rfloor - \lfloor 210\{,000\{,000\} \rfloor$ |
| $\lfloor R_d \rfloor$ | $\lfloor 280\{,000\} \rfloor$ (or $\lfloor 160\{,000\} \rfloor$ if lower)    |
| Player impact         | Smaller absolute rewards; competition still matters                          |
| Sustainability        | Step-down automatically extends life                                         |

### Scenario C — Low treasury / protection mode

| Item                | Value                                                                                                                                                                                          |
|---------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| $\lfloor G \rfloor$ | $\lfloor 15\{,000\{,000\} \rfloor \lfloor e \ G < 60\{,000\{,000\} \rfloor \rightarrow \lfloor R_d=80\{,000\} \rfloor; \lfloor G < 15\{,000\{,000\} \rfloor \rightarrow \lfloor R_d=0 \rfloor$ |
| Player impact       | Minimal or <b>no</b> Commit (safe mode)                                                                                                                                                        |
| Sustainability      | Protocol prioritizes Treasury recovery (e.g. sinks) over emission                                                                                                                              |

## 9. Claim Path (economic settlement)

```
Gameplay → finalizeDay (reserve playerTotal from G)
           → creditBatch (book claimable[tokenId])
           → claim / claimMany (Treasury pays $HANSOME to player)
```

RewardDistributor holds **no** token inventory; it only tracks claimable balances. Double-claim is prevented by zeroing claimable before transfer.

---

## 10. Risks (non-exhaustive)

---

- NFT and token prices are volatile; rewards in HANSOME  $\neq$  fiat profit.
  - Missed Reveal  $\rightarrow$  zero reward for that NFT that day.
  - Safe mode can halt Commits.
  - Population imbalance can compress one side's EV.
  - Smart-contract / operational / market risks remain.
  - This model does **not** cover off-chain speculation or leveraged products.
-
